

## Recap: MDPs Markov decision processes: States S Actions A Transitions P(s'|s,a) (or T(s,a,s')) Rewards R(s,a,s') (and discount \( \gamma\) Start state s Quantities: Policy = map of states to actions Utility = sum of discounted rewards Values = expected future utility from a state (max node) Q-Values = expected future utility from a q-state (chance node)

## The Bellman Equations How to be optimal: Step 1: Take correct first action Step 2: Keep being optimal

## The Bellman Equations

 Definition of "optimal utility" via expectimax recurrence gives a simple one-step lookahead relationship amongst optimal utility values

The arrangest optimal utility values 
$$V^*(s) = \max_a Q^*(s,a)$$
 
$$Q^*(s,a) = \sum_{s'} T(s,a,s') \left[ R(s,a,s') + \gamma V^*(s') \right]$$
 
$$V^*(s) = \max_a \sum_{s'} T(s,a,s') \left[ R(s,a,s') + \gamma V^*(s') \right]$$

• These are the Bellman equations, and they characterize optimal values in a way we'll use over and over

## Value Iteration

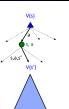

Bellman equations characterize the optimal values:

$$V^*(s) = \max_{a} \sum_{s'} T(s, a, s') \left[ R(s, a, s') + \gamma V^*(s') \right]$$

• Value iteration computes them:

$$V_{k+1}(s) \leftarrow \max_{a} \sum_{s'} T(s, a, s') \left[ R(s, a, s') + \gamma V_k(s') \right]$$

- Value iteration is just a fixed point solution method
- ... though the V<sub>k</sub> vectors are also interpretable as time-limited values

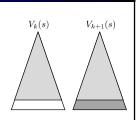

## Convergence\*

- Case 1: If the tree has maximum depth M, then V<sub>M</sub> holds
- Case 2: If the discount is less than 1
  - Sketch: For any state V<sub>k</sub> and V<sub>k+1</sub> can be viewed as depth k+1 expectimax results in nearly identical search trees
  - The difference is that on the bottom layer, V<sub>k+1</sub> has actual rewards while V<sub>k</sub> has zeros

  - That last layer is at best all R<sub>MAX</sub>

    It is at worst R<sub>MIN</sub>

    But everything is discounted by y<sup>k</sup> that far out
  - So V<sub>k</sub> and V<sub>k+1</sub> are at most y<sup>k</sup> max|R| different
     So as k increases, the values converge

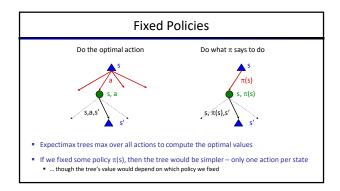

### Question

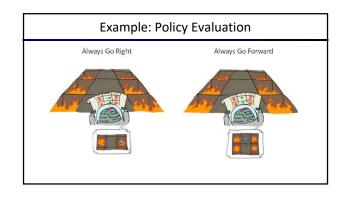

- Suppose that, there is a game that you repeatedly draw a card (with replacement) that is equally likely to be a 2, 3, or 4. You can either Draw or Stop if the total score of the cards you have drawn is less than 6. If your total score is 6 or higher, the game ends, and you receive a utility of 0. When you Stop, your utility is equal to your total score (up to 5), and the game ends. When you Draw, you receive no utility. There is no discount (\gamma = 1).
- Formulate this problem as an MDP with the following states:
  - 0, 2, 3, 4, 5 and a Done state, for when the game ends.
- What is the transition function and the reward function for this MDP?
- Find the optimal values of each state for first 4 iterations
- What is the optimal policy

# **Policy Methods**

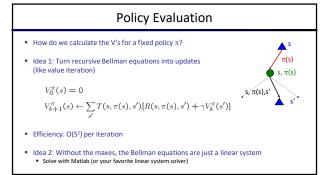

# Policy Evaluation

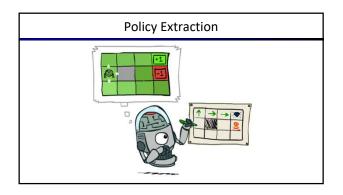

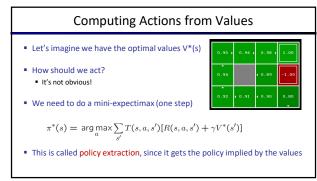

## Utilities for a Fixed Policy Another basic operation: compute the utility of a state s under a fixed (generally non-optimal) policy Define the utility of a state s, under a fixed policy $\pi$ : $V^{\pi}(s) = \text{expected total discounted rewards starting in s and following } \pi$ Recursive relation (one-step look-ahead / Bellman equation): $V^{\pi}(s) = \sum_{s'} T(s, \pi(s), s') [R(s, \pi(s), s') + \gamma V^{\pi}(s')]$

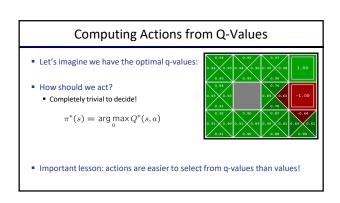

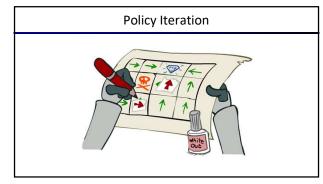

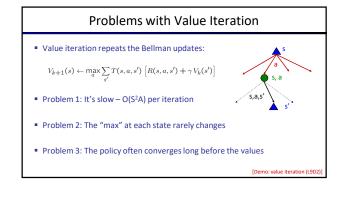

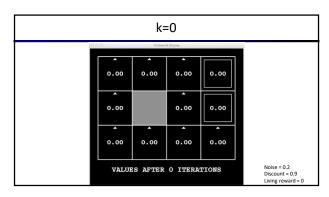

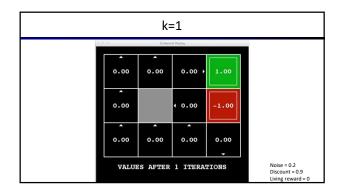

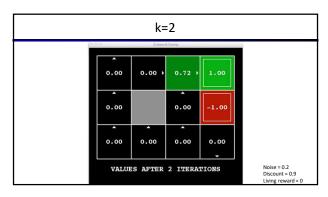

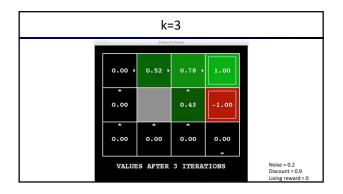

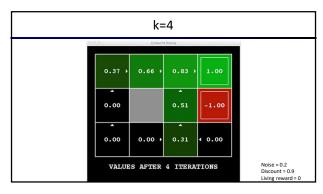

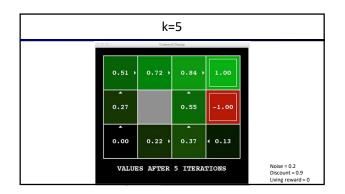

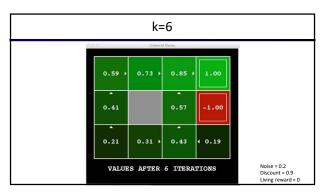

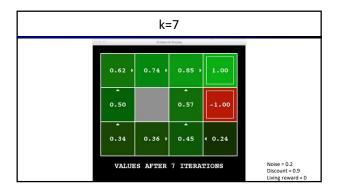

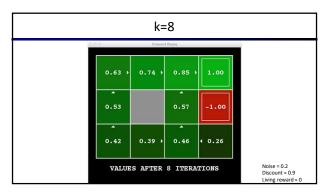

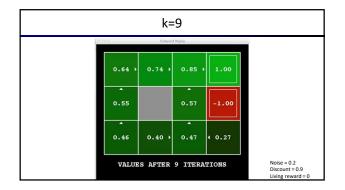

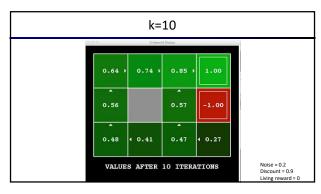

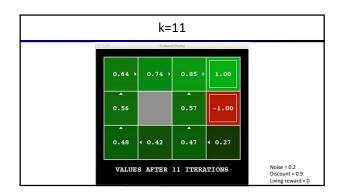

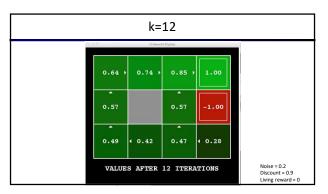

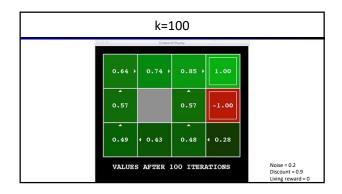

## **Policy Iteration**

- Alternative approach for optimal values:
  - Step 1: Policy evaluation: calculate utilities for some fixed policy (not optimal utilities!) until convergence
  - Step 2: Policy improvement: update policy using one-step look-ahead with resulting converged (but not optimal!) utilities as future values
  - Repeat steps until policy converges
- This is policy iteration
  - It's still optimal!
  - Can converge (much) faster under some conditions

## **Policy Iteration**

- Evaluation: For fixed current policy  $\pi$ , find values with policy evaluation:
  - Iterate until values converge:

$$V_{k+1}^{\pi_i}(s) \leftarrow \sum_{s'} T(s, \pi_i(s), s') \left[ R(s, \pi_i(s), s') + \gamma V_k^{\pi_i}(s') \right]$$

- Improvement: For fixed values, get a better policy using policy extraction
  - One-step look-ahead:

$$\pi_{i+1}(s) = \arg\max_{a} \sum_{\prime} T(s,a,s') \left[ R(s,a,s') + \gamma V^{\pi_i}(s') \right]$$

### Comparison

- Both value iteration and policy iteration compute the same thing (all optimal values)
- In value iteration:
- Every iteration updates both the values and (implicitly) the policy
- $\, \blacksquare \,$  We don't track the policy, but taking the max over actions implicitly recomputes it
- In policy iteration:
  - We do several passes that update utilities with fixed policy (each pass is fast because we consider only one action, not all of them)
  - After the policy is evaluated, a new policy is chosen (slow like a value iteration pass)
  - The new policy will be better (or we're done)
- Both are dynamic programs for solving MDPs

## Summary: MDP Algorithms

- So you want to..
  - Compute optimal values: use value iteration or policy iteration
  - Compute values for a particular policy: use policy evaluation
  - Turn your values into a policy: use policy extraction (one-step lookahead)
- These all look the same!
  - They basically are they are all variations of Bellman updates
  - They all use one-step lookahead expectimax fragments
  - They differ only in whether we plug in a fixed policy or max over actions
